THE ASSESSMENT OF FASCIOILA GIGANTICA INFECTION IN THE RABBIT (ORYCTOLAGUS CUNICULUS) AS A LABORATORY MODEL PARASITE DEVELOPMENT - CLINICAL SYMPTOMS AND LIVER PATHOLOGY

IN THIS STUDY, THE RABBIT WAS ASSESSED AS A LABORATORY HOST FOR THE HELMITHESES PARASITE, FASCIOILA GIGANTICA. THREE GROUPS OF RABBITS WERE INFECTED EXPERIMENTALLY WITH 5, 10 AND 15 METACERCARIAE OF F. GIGANTICA RESPECTIVELY. CLINICAL SIGNS FOUND INCLUDED HAEMORRHAGE AND SCATTERED CALCIATED NODULES ON THE OMENTUM. ECHYMOSIS, FIBROSIS AND NECROSIS WERE PROMINENT ON THE LIVER IN ADDITION TO FIBROSIS AND THICKENING OF THE GALL BLADDER AND BILE DUCTS. HISTOPATHOLOGY OF THE LIVER REVEALED CONGESTION, HEMORRHAGE, CELLULAR INFILTRATION AND NECROSIS. BILE DUCTS WERE HYPERPLASTIC AND FIBROTIC WITH SEVERE INFAMMATORY REACTIONS. THE OVA OF GIGANTICA WERE RECOVERED FROM THE FACES OF SOME INFECTED RABBITS AT 10 WEEKS POST INFECTION. MEAN NUMBER OF FLUKES RECOVERED FROM THE RABBITS WAS 0 IN THE 5 METACERCARIAE GROUP, 2 IN THE 10 METACERCARIAE GROUP AND 5 IN THE GROUP GIVEN 15 METACERCARIAE.

KEYWORDS: FASCIOILA GIGANTICA FASCIOILIASES, RABBIT, LABORATORY MODEL. RUNNING TITLE: FASCIOILIASES IN RABBITS

INTRODUCTION

Fascioliasis, the disease caused by Fasciola gigantica and Fasciola hepatica constitutes one of the most important helminthic diseases of livestock, especially the natural ruminant hosts. The disease is of great economic importance due to the mortality which occurs in acute cases and the morbidity encountered in chronic cases Graber, 1971 and Cawdery, 1976. The recognized importance of fascioliasis has stimulated continued research and the veterinary literature is almost replete with studies on various aspects of the disease.

F. hepatica, the temperate species is the better known of the two. It has been extensively studied in the natural ruminant hosts and various laboratory models such as rabbit, guinea pig, and rats have been developed for this trematode infection. However this is not true for F. gigantica which is the much more important species in tropical Africa and Asia. Previous studies in laboratory hosts seem to reveal that laboratory animals are susceptible to F. hepatica but refractory to F. gigantica, Gerber et al., 1974; Strivasta and Singh, 1974. Furthermore, it was observed that when the development of F. gigantica occurred in laboratory animals' growth did not progress to sexual maturity, Ogunrinade, 1978.

The availability of cheap and easy-to-handle laboratory hosts facilitates rapid advances, in the understanding of the biology and immunology of parasitic infections especially at the cellular and molecular level. For instance an inventory of the literature is almost replete with studies on various aspects of the disease.

RESULTS

Clinical Symptoms: No clinical signs were observed during the first 6 weeks after infection. The parasite materials consist of metacercariae obtained from Lymnaea natalensis 33 days after infection with F. gigantica miracidia. Faecal examination was carried out using the sedimentation method of Thienpont et al., 1979. Histopathology was carried out on tissue samples obtained from the liver of the rabbits and preserved in 10% formalin.

Post Mortem Findings: The post mortem findings included haemorrhage and scattered calcified nodules on the omentum, liver, diaphragm and stomach walls. Severe adhesions between the organs occurred in few cases. Bile ducts and gall bladder were fibrotic and thickened. Echymosis, necrosis and severe fibrosis were observed on the liver. Abscesses were found on the organ in two cases (Fig. 1). The adult and immature flukes were recovered from the bile duct and gall bladder at post mortem. (Fig 2).

Histopathology revealed hepatic congestion, haemorrhage, lymphocytic infiltration, pseudolobulation and necrosis of liver cells were observed as prominent features. Bile duct hyperplasia with severe inflammatory reactions characterised by zones of necrosis surrounded by infiltration of eosinophils and lymphocytes with extensive fibrosis also occurred in the liver. (Fig. 3).

The ova of gigantica were recovered from the faces of infected rabbits as from 10 weeks after infection (Fig 4). Number of flukes recovered at post mortem ranged from 0 to 1 in the 5 metacercarial group, 0 to 4 in those infected with 10 metacercariae and 2 to 8 in the group infected with 15 metacercariae.

DISCUSSION
In this study, rabbits were infected experimentally with F. gigantica in order to assess the parasite development, clinical symptoms and liver pathology with the aim of developing these animals into a suitable model as laboratory host for fascioliasis. The gross and histo-pathological findings in the infected rabbits especially as these related to the degree of liver destruction were found to be directly related to the number of flukes recovered at post mortem. The works of Batakana et al., 1976, Uzuokwu and Ikerne, 1978 and Schilihorn Van Veen, 1980, corroborates this.

The result of this study though will seem to negate the findings of some previous author such as Gether et al., 1976, Ogunrinade, 1978 who reported rabbit as being refractory to F. gigantic3 infection. However it was observed that the greater the number of surviving juvenile flukes that reaches the liver (in excess of 3), the lower their growth rate and in some, failure to attain sexual maturity was observed. This is probably as a result of competition for nutrient and space — which in the light of size of the rabbit liver may not permit development to adult stage. Rabbit liver may be up to 11cm at its widest point and adult flukes recovered measured between 30mm — 40mm in length and 6— 7mm in breadth. In the natural ruminant hosts this may reach up to 25— 75mm by 12mm.

The main features observed in rabbits which included anorexia, dullness, weakness, pale mucus membrane, are similar to the findings of Batakana et al., 1976 in the natural ruminant host. However Berry and Dargie, 1977 concluded that symptoms in any host depends on the dose and viability of metacercariae, type of host, age, plane of nutrition and absence or presence of other current infections. These factors could be further examined in the rabbit.

The death recorded at 10 weeks in the 15 metacercaria group of rabbits may not be strange as Bitakarimire and Bwangamoi, 1969 also recorded death at 12 weeks in the cattle infected with F. gigantica metacercariae in excrs of 1000.
